Abstract. The goal of quantum circuits transformation is to construct a mapping from logical quantum circuits to physical ones in acceptable time, and in the mean time use auxiliary gates as few as possible. In this paper, we present an effective approach to construct such a mapping. It has two keys steps. One is applying a combined subgraph isomorphism (CSI) to initialize the mapping, the other is dynamically adjusting the mapping using Tabu Search based transformation (TST). The experiments show the improvement of our method in the following aspects. Comparing the VF2 algorithm, for initializing the mapping, CSI save 22.26% auxiliary gates and reduces the depth of output circuits by 11.76%. (TST) is of more scalable than many state-of-the-art algorithm.

Keywords: Quantum circuit transformation \cdot Subgraph isomorphism \cdot Initial mapping \cdot Tabu Search

1 Introduction

Quantum technology has been applied in practice, but large quantum computers have not yet been built. Most of the contributions of quantum information to computer science are still in the theoretical stage. In March 2017, IBM developed the first 5-qubit backend called IBM QX2. In June, it launched the 16-qubit backend called IBM QX3. The revised versions of 5-qubit and 16-qubit are called IBM QX4 and IBM QX5, respectively. IBM Q Experience provides the public with free quantum computer resources on the cloud and opens source the quantum computing software framework $Qiskit^4$.

The goal of circuit transformation is to execute logical circuits on physical circuits, so logical qubits must be mapped to physical qubits. The biggest problem facing quantum information is the problem of quantum decoherence. Due

^{*} Supported by organization x.

⁴ https://www.qiskit.org/.

to the decoherence problem of qubits, the quantum gates need to complete in a coherent period, and the time of qubits in the coherent state is short. The entanglement of the quantum system with the surrounding environment will lead to quantum decoherence. It is unrealistic to use quantum error correction in the circuit mapping process, since there are only dozens of quantum in the NISQ era [16]. It is necessary to transform circuits by adding auxiliary gates to satisfy logical and physical constraints, since quantum algorithms do not consider any hardware connectivity constraints and quantum circuit transformation is an important part of quantum circuit compilation. Thus we require a set of highly efficient and automatic mapping procedures to handle it. We call the circuit mapping adjustment as circuit transformation. The process may introduce many errors, which brings a huge challenge to circuit compilation because noise has a greater impact on the final circuit and may make the result meaningless. The quantum coherence time is short. The longest coherence time of a superconducting quantum chip is still within 10us-100us, the time of a single quantum gate is about 20ns, the time of a 2-qubit gate is about 40ns, and the time of a measurement operation is about 300ns-1us.

Paler proved that the initial mapping has an important influence on quantum circuit transformation [15]. Paler used a heuristic method to find the initial mapping and IBM's compiler to benchmark. Preliminary results show that just by placing qubits in different positions from the default (trivial placement) in the actual circuit instance on the actual NISQ device, the cost can be reduced by up to 10%. In 2018, Li proposed a novel reverse traversal technique, which determines the initial mapping by considering the entire circuit [9]. Zhou proposed an annealing algorithm to find an initial mapping, but it is unstable [23]. In 2020, Li use VF2 subgraph isomorphism algorithm to generate an initial mapping [10].

The goal of circuit transformation algorithm is to find a minimum number of SWAPs. There are currently five main methods for solving the quantum circuit transformation problem.

Unitary matrix factorization algorithm. The first method uses the unitary matrix factorization algorithm to rearrange the quantum circuit from the beginning while retaining the input circuit [8, 14].

Converting into some existing problems. The second method converts the quantum circuit transformation problem into some existing problems, such as AI planning [22, 3], Integer Linear Programming (ILP) [1], Satisfiability Modulo Theory (SMT) [12]. They use tools to find acceptable results, which cannot take advantage of certain properties of quantum mapping. Furthermore, they may run for a long time and apply to small-scale quantum circuits.

Exact methods. The exact method is only suitable for simple quantum architecture and cannot be extended to complex quantum architecture [19].

Graph theory. In [17], Shafaei used the minimum linear permutation problem in graph theory to model the problem of reducing the interaction distance. It divides a given circuit into several subcircuits and applies the minimum linear permutation problem, respectively. Then it turns non-adjacent gates in the subcircuits into adjacent gates by adding auxiliary gates. Finally, it uses the minimum linear permutation problem to find an appropriate permutation and bubble sort to calculate the number of SWAP gates needed. Guerreschi and Matsuo proposed a two-step method to reduce the quantum circuit transformation to the graph problem to minimize the number of auxiliary gates, based on the graph coloring problem and the largest subgraph isomorphism problem [7,11].

Heuristic search. Heuristic search uses an evaluation function to obtain an acceptable solution in exponential time. Zulehner layered the circuits, grouped the circuits that could be executed in parallel into the same layer, and then determined compatible mappings for each of these layers to add as few auxiliary gates as possible. Zhou designed a heuristic search algorithm with a novel selection mechanism [23]. He did not choose the lowest cost operation to apply but looked forward one step and then chose the best continuous operation. In this way, the algorithm can effectively avoid local minimum. Moreover, a pruning mechanism is introduced to reduce the search space's size and ensure that the program terminates in a reasonable amount of time. This algorithm's time complexity is $O(|V|^4)$.

Li proposed a SWAP-based search algorithm SABRE [9]. Compared with previous search algorithms based on exhaustive mapping, SABRE achieves exponential search complexity and ensures the scalability of SABRE to adapt to the large quantum equipment in the NISQ era. The routing algorithm implemented in $t | ket \rangle$ can ensure that any quantum circuit is compiled into any architecture [4]. The algorithm is divided into four stages: decomposing the input circuit into time steps, determining the initial mapping, routing across time steps, and finally cleaning up. The heuristics in $t|ket\rangle$ give the same or better results than other circuit transformation systems in terms of depth and total number of gates in the compiled circuit, with much shorter running times, and can handle larger circuits. Tannu proposed a variation-aware qubit movement strategy, which takes advantage of the change in error rate and a change-aware quantum circuit transformation strategy by trying to select the route with the lowest probability of failure [21]. This strategy uses the error rate of SWAPto allocate logical qubits to physical qubits, thus avoiding paths with high error rates as much as possible.

We adjust the lifetime of qubits through parallelization, and use Subgraph-Compare to generate partial isomorphic subgraphs of logical circuits and physical circuits as part of the initial mapping. The advantage of the initial mapping result is that we use the appropriate subgraph isomorphism and the two-way connection of the logical circuit and the physical circuit to obtain a dense initial mapping, which avoids certain nodes from being mapped to remote locations. We use Tabu Search to generate circuits that can be executed on physical circuits [6]. Tabu Search can avoid falling into local optimum and swapping the recently swapped qubits, thereby improving the parallelism of quantum gates. We add the SWAPs associated with the gates on the shortest path to the candidate set, which greatly reduces the search space. Therefore, our search speed is so fast. Our heuristic function not only considers the current gates but also the constraints of the behind gates, but needs to control the decisiveness of the

4 F. Author et al.

behind gates in the heuristic function. The main contributions of this paper are as follows.

- 1. We propose a combined subgraph isomorphism algorithm (*CSI*) to generate the initial mapping, which can be reduced to subgraph isomorphism. Thus we use a suitable subgraph isomorphism algorithm to generate part of the initial mapping and then complete the mapping based on the connectivity between qubits.
- 2. We propose a heuristic circuit transformation algorithm based on Tabu Search (*TST*) [6], which can handle large circuits in a short time at a low cost. Compared with the previous precise search and heuristic algorithms, it can complete the circuit transformation in a shorter time.
- 3. We propose a look-ahead heuristic function that considers the factors of the current gates and the behind gates and filters out a swap that is beneficial to the current gates and also brings the behind gates closer.

The rest of this paper is organised as follows. In Section 2 we recall some background of quantum computing and quantum information. We propose the problems of the transformation of quantum circuits in Section 3. Section 4 describes and analyses our algorithm in detail. The experimental results are reported in Section 5. The last section concludes the paper and discusses future research.

2 Background

This section introduces some notions and notations of quantum computing and quantum information.

2.1 Qubits

Classical information store in bits, while quantum information store in qubits. Besides two basic states $|0\rangle$ and $|1\rangle$, a qubit can be in any linear superposition state with the $|\phi\rangle = a\,|0\rangle + b\,|1\rangle$, where $a,b\in\mathbb{C}$ satisfy $|a|^2 + |b|^2 = 1$. Then $|\phi\rangle$ is in the state $|0\rangle$ with the probability $|a|^2$ or in the state $|1\rangle$ with the probability $|b|^2$.

2.2 Quantum Gate

Commonly used quantum gate symbols and their matrices are shown in Fig. 1. A physical qubit or logical qubit is represented by q, q, respectively.

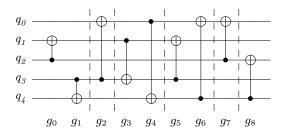

2.3 Quantum Circuit

A quantum logical circuit LC (see Fig. 2) consists of quantum gates interconnected by quantum wires [5]. A quantum wire is a mechanism for moving quantum data from one location to another. Each line represents a qubit, and the

Hadamard gate	——[H]——	$\frac{1}{\sqrt{2}} \left[\begin{array}{cc} 1 & 1 \\ 1 & -1 \end{array} \right]$
Pauli-X gate	X	$\left[\begin{array}{cc} 0 & 1 \\ 1 & 0 \end{array}\right]$
Pauli-Y gate	Y	$\left[\begin{array}{cc} 1 & -i \\ i & 0 \end{array}\right]$
Pauli-Z gate	Z	$\left[\begin{array}{cc} 1 & 0 \\ 0 & -1 \end{array}\right]$
phase gate	S	$\left[\begin{array}{cc} 1 & 0 \\ 0 & i \end{array}\right]$
$\frac{\pi}{8}$ gate	T	$\left[\begin{smallmatrix} 1 & 0 \\ 0 & e^{i\pi/4} \end{smallmatrix} \right]$
CNOT gate		$\left[\begin{array}{cccc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{array}\right]$

Fig. 1. The symbols of common quantum gates and their matrices

gates on the line act on the corresponding qubits. The execution order of a quantum logical circuit graph is from left to right. The width w of a circuit refers to the number of qubits in the circuit. The depth d of a circuit refers to the number of layers executing in parallel. For example, the depth of the circuit (see Fig. 2) is 6, and the width is 5. In this paper, circuits with a depth less than 100 are called small-scale circuits, circuits with a depth greater than 1000 are called large-scale circuits, and the rest are medium-scale circuits. It is unnecessary to consider single quantum gates in circuit transformation, since the single qubit is local [18].

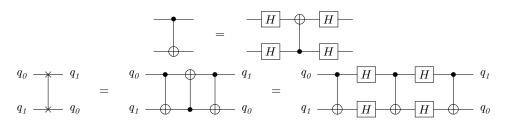

Fig. 5. The above circuit changes the direction of the CNOT gate by adding four H gates, and below is the circuit of the SWAP gate.

2.4 Architectures

We mainly discuss the physical circuits of IBM Q series. Let $\mathcal{AG}_{\mathcal{P}} = (V_P, E_P)$ denote the architecture graph of the physical circuit, where V_P denotes the physical qubit set and E_P denotes the edge set that the CNOT gates. Fig. 6 (a) and (b) are PAG of the 5-qubit of IBM QX2, (c) and (d) are PAG of 16-qubit of IBM QX3, and (e) is the PAG of IBM Q20. The arrow direction in the figure indicates the control direction of the gate, and the 2-qubit gate can only be performed between qubits with edges connected. IBM physical circuits only support single quantum gates and CNOT gates between two adjacent qubits.

Given a logical circuit LC, a physical structure \mathcal{AG}_P , an initial mapping τ , and a CNOT gate $g = \langle q_i, q_j \rangle$, where q_i is the control qubit, q_j is the target qubit. $\langle \tau(q_i), \tau(q_j) \rangle$ is a directed edge on \mathcal{AG}_P , if gate g is executable.

Example 1. Fig. 4 (a) is the logical structure of Fig. 2, Fig. 4 (b) is the partial architecture graph of IBM Q20, the initial mapping is $\tau = \{q_0 \to q_{10}, q_1 \to q_0, q_2 \to q_6, q_3 \to q_5, q_4 \to q_{11}\}$. $g_0 = \langle q_2, q_1 \rangle$ is not executable, since the edge $\langle \tau(q_2), \tau(q_1) \rangle = \langle q_6, q_0 \rangle$ does not exist in \mathcal{AG}_P . But $g_3 = \langle q_1, q_3 \rangle$ is executable, since the edge $\langle \tau(q_1), \tau(q_3) \rangle = \langle q_0, q_5 \rangle$ exist in \mathcal{AG}_P .

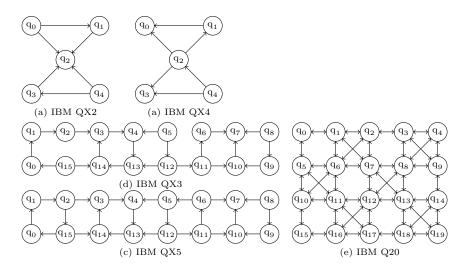

Fig. 6. IBM QX architectures

3 Problem Analysis

Single qubit gates and CNOT gates are used as basic gates, since they are commonly used to implement any quantum circuit supported by the IBM QX architecture. Before circuit transformation, the circuit should be simplified to a circuit with only single quantum gates and CNOT gates [13, 2]. We insert auxiliary gates (see Fig. 5) to move two non-adjacent quantum positions to adjacent positions or change the direction of the CNOT gate, but this process may introduce errors. The introduction of auxiliary gates may lead to errors. We hope to find a circuit transformation algorithm to make the output circuit with the minimum number of auxiliary gates and the circuit depth in an acceptable amount of time. A quantum circuit transformation problem mainly includes the following four steps. Isomorphism and transformation are both NPCs [19].

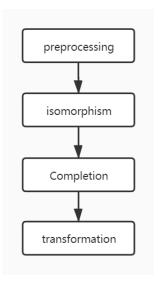

Fig. 7. Circuit transformation process

- 1. Preprocess the logical quantum circuit. It includes extracting the logical architecture graph (LAG) of the circuit, adjusting the life cycle of qubits (the work is done by Zhang [24]), and calculating the shortest paths of the physical circuit.
- 2. Compute isomorphic substructures. It uses the subgraph isomorphism algorithm to find part of the initial mapping, which is done by Sun [20].
- 3. Generate a high-quality initial mapping. We perform mapping completion because the remaining nodes cannot satisfy all isomorphism requirements. According to the connectivity between the unmapped node and the mapped nodes. Unmapped nodes are mapped to the neighborhood of mapped nodes, which satisfies the connectivity of part of the LAG and PAG and reduces the length of the shortest path.
- 4. Transforming logical circuits to meet physical constraints. Circuit transformation need to be solved before quantum circuits compilation, since he design of quantum algorithms does not refer to the connectivity constraints of any hardware. Therefore, It is necessary for any quantum compiler.

4 Solution

The solution proposed in this paper mainly includes preprocessing, initial mapping, and circuit transformation. In this section, we will introduce them in detail.

4.1 Preprocessing

Before circuit transformation, we can preprocess it to get more convenient data to shorten our search time and space. In the preprocessing, we adjust the circuit of the input open QASM program to shorten the life cycle of qubits. Then we use Breadth-First Search (BFS) to calculate the shortest distance between each node on the architecture graph.

Circuit Adjustment We use a layered method to analyze the life cycle of qubits and pack the gates that can be executed in parallel into a bundle, forming a layered bundle format [24]. A conversion method is designed to use the layered bundle format to determine which gates can be moved, which reduces the life cycle of these qubits. The algorithm reduces the error rate of quantum programs by 11%. In most quantum workloads, the longest qubit lifetime and the average qubit lifetime can be reduced by more than 20%, and the execution time of some quantum programs can also be reduced.

Shortest Distance Given PAG and the distance of each edge is 1, we can use Floyd-Warshall algorithm calculate the shortest distance matrix dist[i][j], which represents the shortest distance from q_i to q_i .

For IBM QX2, QX3, QX4, QX5, a SWAP needs 7 gates (3 CNOT gates and 4 H gates). Only 4 H gates are needed to change the direction of an adjacent CNOT gate. For a CNOT gate $g = \langle q_i, q_j \rangle$, two qubits are mapped to \mathbf{q}_m and \mathbf{q}_n , respectively, with $\tau(q_i) = \mathbf{q}_m$, $\tau(q_j) = \mathbf{q}_n$. Then the cost of executing g under the shortest distance path is $cost_{cnot}(q_i, q_j) = 7 \times (dist[m][n] - 1)$. For IBM Q20, in which all edges are bidirectional, a SWAP requires 3 CNOT gates. Thus the cost between them is $cost_{cnot}(q_i, q_j) = 3 \times (dist[m][n] - 1)$. The time complexity is $O(N^3)$.

Example 2. Take the QX5 structure as an example. Suppose there is a CNOT gate $g = \langle q_i, q_j \rangle$, q_i is mapped to q_1 , q_j is mapped to q_{14} , and the shortest distance between them is dist[1][14] = 3. There are 3 shortest paths to move q_1 to the adjacent position of q_{14} : $\Pi = \{\pi_0, \pi_1, \pi_2\}$, $\pi_0 = q_1 \rightarrow q_2 \rightarrow q_3 \rightarrow q_{14}$, $\pi_1 = q_1 \rightarrow q_2 \rightarrow q_{15} \rightarrow q_{14}$, $\pi_2 = q_1 \rightarrow q_0 \rightarrow q_{15} \rightarrow q_{14}$. Their costs are $cost_{\pi_0} = 18$, $cost_{\pi_1} = 14$, $cost_{\pi_2} = 14$, respectively.

Circuit Layering Quantum gates acting on different qubits can execute in parallel. Therefore, we classify the gates that can be executed in parallel into one layer, otherwise add a new layer. $L(LC) = \{\mathcal{L}_0, \mathcal{L}_1, ..., \mathcal{L}_n\}$ represents the layered circuit, where \mathcal{L}_i $(0 \le i \le n)$ represents a quantum gate set that can be executed in parallel. The quantum gate set separated by the dotted line in Fig. 2 are the following $\mathcal{L}_0 = \{g_0, g_1\}, \mathcal{L}_1 = \{g_2\}, \mathcal{L}_2 = \{g_3, g_4\}, \mathcal{L}_3 = \{g_5, g_6\}, \mathcal{L}_4 = \{g_7\}, \mathcal{L}_5 = \{g_8\}.$

At the same time, we generate logical circuit architecture graph $\mathcal{AG}_{\mathcal{L}} = (V_L, E_L)$, which is an undirected graph. V_L contains the vertices and the degree of each vertex, and E_L represents the set of undirected edges that the CNOT gates can execute.

4.2 Initial Mapping

It has been proved that the initial mapping has an important influence on quantum circuit transformation, and the subgraph isomorphism can be reduced to initial mapping problem. Thus we use the subgraph isomorphism algorithm to find a partial initial mapping that helps to minimize auxiliary gates added by the output circuit.

In PAG, it is almost impossible to find a subgraph that exactly matched nodes LAG. Thus we regard the mapping with the largest number of matching nodes as the partial mapping. SubgraphCompare [20] compares several state-of-the-art subgraph isomorphism algorithm composition. It shows that using the filters and sorting ideas of GraphQL algorithm to process candidate nodes, and the local candidates calculation method LFTJ based on set-intersection to enumerate the results is the best. We artificially connect the isolating qubits to the qubits with the largest degree in the logical architecture graph, since SubgraphCompare cannot handle the not connected graph. We want to minimize the impact of logical dependency graph, so match it with the node with the largest degree.

The input of Algorithm 1 is a target graph (\mathcal{AG}_P) , a query graph (\mathcal{AG}_L) , and the partial mappings T. First, we initialize an empty queue Q. Then we traverse τ and add the unmapped nodes to the queue Q. For the unmapped nodes, we try to map them to the vicinity of the mapped nodes in \mathcal{AG}_P . Finally, generate a dense mapping, which can reduce the added auxiliary gates. We would try to match the remaining unmapped nodes randomly, but it may lead to mapping to a node far away from other nodes. If the unmapped node has an edge adjacent to the matched point in the query graph, it will be matched to one of the adjacent nodes first. Finally, we get all initial candidate mappings.

In Algorithm 1, lines 2 selects the partial mapping with the most mapped nodes l as the candidate set. Lines 3-41 completes the logical qubit unmapped nodes in the candidate set. In line 6, we initialized an empty queue Q, which stores unmapped logical qubits. In lines 8-13, we traverse the mapping τ and add the unmapped qubits to Q. We loop until Q is empty, and all logical qubits map to physical qubits. We take out the first element in Q to q. Lines 16 and 17 are used to get the adjacency matrices of \mathcal{AG}_P and \mathcal{AG}_L , respectively. Line 18 initializes an empty map cans, sort by descending order of whether q_m is mapped and the number of gate appearances. Lines 20-22 store the nodes q_m connected to q in the adjacency matrix in cans. Lines 23-38 traverse the cans, select the node q_m has been mapped to the node (cans.first) on PAG, and it has the largest number of connections to q in the cans. q is the node where q_m is mapped to PAG in τ . Line 26 deletes the node from cans. Lines 27-34 select the node k adjacent to the q in the adjacency matrix, and map the q to the node.

Example 3. Following the previous example, we first use CSI algorithm for LAG (see Fig. 4 (a)) and PAG (see Fig. 6 (e)) to obtain the partial mapping set $T = \{\tau_0, \tau_1, ..., \tau_n\}$. Then we use one of the partial mappings as an example $\tau_0 = \{q_0 \to \mathbf{q}_{10}, q_1 \to -1, q_2 \to \mathbf{q}_6, q_3 \to \mathbf{q}_5, q_4 \to \mathbf{q}_{11}\}, \ 0 \le i < n. \ q_1 \to -1$ means that q_1 is not mapped to the physical node, so we need to perform mapping completion. In the example, the maximum number of mapped nodes is 4.

Algorithm 1: initial mapping algorithm CSI

```
Input: \mathcal{AG}_{\mathcal{L}}: The architecture of logical circuit

         if l = \tau.length then
 4
              result.add(\tau);
 5
              Q \leftarrow initialing an empty unmapped node queue
 6
              i \leftarrow 1;
 7
              while i \leq \tau.length do
 8
                   if \tau[i] = -1 then
  9
10
                        Q \leftarrow i;
                   end
11
                   i \leftarrow i + 1;
12
              end
13
              while Q is not empty do
14
                   int q \leftarrow Q.poll();
15
                   targetAdj \leftarrow \mathcal{AG}_{\mathcal{P}}.adjacencyMatrix();
16
                   queryAdj \leftarrow \mathcal{AG}_{\mathcal{L}}.adjacencyMatrix();
17
                   cans \leftarrow initialing an empty candidate node list;
                                                                                       // sorted by
18
                    the connectivity of nodes
19
                   foreach q_m \leq queryAdj[q].length do
                        cans \leftarrow cans \cup \{q_m\};
20
21
                   end
                   while cans is not empty do
22
                        q \leftarrow \tau[cans.first];
23
                        k \leftarrow 0;
\mathbf{24}
                        cans \leftarrow cans \backslash cans.first;
25
                        while k < targetAdj[q].length do
26
                             if (targetAdj[q][k] \neq -1 \text{ or } targetAdj[k][q] \neq -1)
27
                              and not \tau.contains(k) then
28
                                  \tau[q] \leftarrow k;
29
                                  break;
30
                             end
31
                             k \leftarrow k + 1;
32
                        \mathbf{end}
33
                        if k \neq targetAdj[q].length then
34
                            break;
35
36
                        end
37
                   end
              end
38
39
         \mathbf{end}
40 end
```

Next, we demonstrate how τ_0 is completed. We add all unmapped nodes to the queue $Q,\ Q=\{q_1\}$, and the loop ends until Q is empty. We put the first element of Q into q, and delete it from Q. Then we get the adjacency matrix of the query graph and the target graph, and traversing the adjacency matrix. We put the nodes q_m adjacent to q into the candidate nodes list cans, which is sorted by the connectivity of q_m and q. We get $cans=\{q_3,q_2,q_4,q_0\}$. Thereafter, we traverse cans and take out of the first element $value=q_3$ in cans, and calculate the phycical node $q=q_5,\ \tau_0(q_3)=q_5$. Finally, we map q to the node connected to q and not yet mapped. If the nodes connected to q have been mapped, the loop continues. In this example, it can be directly mapped to q_0 . In the end, we get $\tau_0=\{q_0\to q_{10},q_1\to q_0,q_2\to q_6,q_3\to q_5,q_4\to q_{11}\}$.

4.3 Swap Minimization

Tabu Search Tabu Search algorithm is a type of heuristic algorithm. Tabu Search uses a tabu list to avoid searching for repeat space, thereby avoiding deadlock. The algorithm uses amnesty rules to jump out of the local optimum to ensure the diversity of transformed results. The circuit transformation mainly relies on the Tabu Search algorithm, aiming to deal with the large-scale circuits that the current algorithm is difficult to handle and the output circuit closer to the optimum solution in a short time.

There are mainly the following objects in Tabu Search: neighborhood field, neighborhood action, tabu list, candidate set, tabu object, evaluation function, and amnesty rule. All the edges that can be swapped in the current map are the neighborhood fields. The tabu list avoids local optimum and guarantees the parallelism of auxiliary gates. The tabu object is the object in the tabu list. We try not to use the recently swapped qubits as much as possible, which are added to the tabu list. We perform pruning to save search space, because only swaps adjacent to at least one gate node are meaningful. We select the edge in the shortest path that has an intersection with the qubits contained in the gate as the candidate set. The evaluation function selects a SWAP evaluation formula from the candidate set, generally taking the objective function as the evaluation function. The evaluation function satisfies some gates, and the number of SWAP gates added or the depth of the entire circuit should be small. The amnesty rule use when all objects in the candidate set are banned, or after banning an object, the target value will be greatly reduced.

The calculation of the neighborhood fields is shown in Algorithm 2. The input is the current circuit mapping τ_p , qubits represents the mapping of physical qubits to logical qubits, Where j=qubits[i] means that the i-th physical qubit has been mapped to the j-th logical qubit. locations represents the mapping of logical qubits to physical qubits, Where j=locations[i] means that the i-th logical qubit has been mapped to the j-th physical qubit. The current layer list of all gates cl, and the output is a candidate set of the current mapping. E is the edge of all the shortest paths in the physical architecture graph of all gates in the current layer. Lines 17-37 swap all the edges of candidate set, and calculate the cost of them.

Example 4. Under the mapping $\tau_0 = \{q_0 \to q_{10}, q_1 \to q_0, q_2 \to q_6, q_3 \to q_5, q_4 \to q_{11}\}$, for $L_0 = \{g_0, g_1\}$, $dist_{cnot}(g_0) = 3$, $dist_{cnot}(g_1) = 3$. Gate g_1 can execute directly in the τ_0 mapping, so we delete it from L_0 , but g_0 cannot execute in the mapping τ_0 . Thus circuit transformation is required. Nodes that cannot be executable join the set $swap_nodes = \{q_0, q_6\}$ The shortest path is $paths = \{\{q_6 \to q_1 \to q_0\}, \{q_6 \to q_5 \to q_0\}\}$, and then we traverse the shortest path to calculate candidate set. The two endpoints of the edge passed by the shortest path should intersect the swap set and join the candidate set. so the current candidate set is $\{SWAP(q_6, q_1), SWAP(q_1, q_0), SWAP(q_6, q_5), SWAP(q_5, q_0)\}$.

The circuit mapping algorithm based on Tabu Search takes a layered circuit and an initial mapping as input and outputs a circuit that can be executed in the specified architecture graph(see Algorithm 3). The transformed circuit mapping of each layer is used as the initial mapping of the next layer circuit. Lines 2 to 3 regard the initial mapping τ_{ini} as the best mapping τ_{best} and the current mapping τ_{curr} . Lines 4 to 17 cyclically check whether all the current layer gates can execute under the mapping τ_{curr} . If it does not satisfy the execution of all gates or the number of iterations has not reached the given maximum number, the search will continue. Otherwise, the search will terminate. Line 5 gets the current mapping candidate, and line 6 finds the best mapping in the candidate set. The mapping will first remove the overlapping elements of the candidate set and the tabu list. Then from the remaining candidates, we choose a mapping with the lowest cost. Lines 7 to 12 are the amnesty rules. When the best candidate is not found, the candidate set elements are all the same as the tabu list elements. The amnesty rule selects the lowest cost mapping in the candidate set as the best candidate mapping. Lines 13-16 update the best mapping τ_{best} and the current mapping τ_{curr} , and add the SWAP performed by the best mapping to the tabu list tl, indicating that the SWAP has just been performed. The algorithm would try to avoid re-SWAP the just swapped qubits. Then it will judge whether the algorithm stop condition is satisfied. The stopping condition determines whether the number of iterations has reached the maximum number, or the current mapping satisfies the execution of all gates in the current layer. If the stop condition is not satisfied, continue to loop.

Example 5. Continue to the previous example. We start searching from the initial mapping. We need to get the candidate SWAP set and select the one with the lower evaluation scores. For $L_0 = \{g_0, g_1\}$, the candidate set is $\{SWAP(\mathbf{q}_6, \mathbf{q}_1), SWAP(\mathbf{q}_1, \mathbf{q}_0), SWAP(\mathbf{q}_6, \mathbf{q}_5), SWAP(\mathbf{q}_5, \mathbf{q}_0)\}$, and the costs are $cost(SWAP(\mathbf{q}_6, \mathbf{q}_1)) = 3.0$, $cost(SWAP(\mathbf{q}_1, \mathbf{q}_0)) = 3.0$, $cost(SWAP(\mathbf{q}_6, \mathbf{q}_5)) = 3.0$, $cost(SWAP(\mathbf{q}_5, \mathbf{q}_0)) = 3.0$, respectively. The algorithm will choose the first SWAP, the mapping becomes $\tau_0 = \{q_0 \to \mathbf{q}_{10}, q_1 \to \mathbf{q}_0, q_2 \to \mathbf{q}_1, q_3 \to \mathbf{q}_5, q_4 \to \mathbf{q}_{11}\}$. The algorithm loops to determine whether it reachs the stop condition. It can be seen that the current mapping has satisfied the execution of g_0 . Continue to search for the next layer.

Algorithm 2: Calculate the candidate sets

```
Input: dist: The shortest paths of physical architecture
    qubits: The mapping from physical qubits to logical qubits
    locations: The mapping from logical qubits to physical qubits
    cl: Gates included in the current layer of circuits
    Output: results: The set of candidate solution
 1 Initialize results \leftarrow \emptyset;
 2 E_w \leftarrow \text{Calculate the weight of each edge}
 swap\_nodes \leftarrow An empty set of candidate swap nodes
 4 foreach g \in cl do
         q_1 \leftarrow locations[g.control];
 5
         q_{\textit{2}} \leftarrow locations[g.target];
 6
 7
        if g is executable then
             cl \leftarrow cl \backslash g;
 8
             continue;
 9
10
         end
         swap\_nodes.add(q_t);
11
         swap\_nodes.add(q_2);
12
13 end
14 foreach g \in cl do
15
         q_1 \leftarrow locations[g.control];
16
         q_{2} \leftarrow locations[g.target];
         foreach path \in paths[q_1][q_2] do
17
             foreach e \in path do
18
                  if swap\_nodes.contains(sour\_node) or
19
                   swap\_nodes.contains(tar\_node) then
20
                      new\_qubits \leftarrow qubits;
21
                      new\_locations \leftarrow locations;
\mathbf{22}
                       q_1 \leftarrow new\_qubits[e.source];
                       q_{2} \leftarrow new\_qubits[e.target];
23
                      new\_qubits[e.source] \leftarrow q_2 \; ;
24
                      new\_qubits[e.target] \leftarrow q_{\mathit{1}};
25
                      if q_1 \neq -1 then
26
                        new\_locations[q_1] \leftarrow q_2;
27
                      end
\mathbf{28}
                      if q_2 \neq -1 then
29
                       | new\_locations[q_2] \leftarrow q_1;
30
                      end
31
                      s \leftarrow \emptyset:
32
                      s.value \leftarrow compute\_evaluate\_value(dist, new\_locations, cl);
33
                      results \leftarrow results \cup s;
34
                  end
35
36
             end
        end
37
38 end
39 return results;
```

Algorithm 3: Tabu Search

```
Input: \tau_{ini}: The initial mapping
    tl: Tabu list
    Output: \tau_{best}: The final state and SWAPs
  1 Initialize \tau_{best} \leftarrow \tau_{ini};
  \mathbf{2} \ \tau_{curr} \leftarrow \tau_{ini} \ ;
 3 iter \leftarrow 1;
                                                                          // Number of iterations
 4 while not mustStop(iter, \tau_{best}) do
          C \leftarrow \tau_{curr}.candidates();
                                                                                      // candidate set

          tl \leftarrow tl \cup \{C_{best}.swap\};
15
          iter \leftarrow iter + 1;
17 end
18 return \tau_{best}
```

Evaluation function design We can control the search direction by changing the evaluation function. We test two evaluation functions, one uses the depth of the generated circuit as the evaluation criterion (2), and the other uses the number of auxiliary gates in the generated circuit as the evaluation criterion (1).

$$cost(SWAP(q_m, q_n)) = \sum_{g \in L_i} (dist[g.control][g.target])$$
 (1)

$$cost(SWAP(q_i, q_i)) = Depth(L_i)$$
(2)

 $cost(SWAP(q_i, q_j))$ represents the cost of executing all gates of the current layer L_i after swapping q_i , q_j . We only calculate the distance of the unmapped gates of the after the SWAP as in the equation (2) or the depth between the unmapped gates as in the equation (1).

Look ahead We deserve that the number of gates in each layer after layering is small. The output of the i-th (i < n) layer is used as the input of the (i+1)-th layer. Note that the swap algorithm of the i-th layer will affect the mapping of the (i+1)-th layer. If we only consider the gates of current layer when choosing the swap, the swap only satisfies the requirement of the i-th layer. Thus we take the circuit of the (i+x)-th (i+x < n) layer into consideration. However, it is necessary to give priority to the execution of the gates of the i-th layer, so we introduce an attenuation factor δ , which controls the influence of the (i+x)-th

layer gates. Experiments show that for $x=2,\ \delta=0.9$, the final effect is the best. Our evaluation function can be rewritten as

$$cost(SWAP(q_m, q_n)) = \sum_{g \in L_i} (dist[g.control][g.target]) + \\ \delta \times \sum_{j=i}^{i+x} \sum_{g \in L_j} (dist[g.control][g.target])$$

$$(3)$$

$$cost(SWAP(\mathbf{q_m}, \mathbf{q_n})) = Depth(L_i) + \delta \times Depth(\sum_{j=i}^{i+x} L_j). \tag{4}$$

Complexity Given logical circuit architecture graph $\mathcal{AG}_{\mathcal{L}} = (V_L, E_L)$, physical circuit architecture graph $\mathcal{AG}_{\mathcal{P}} = (V_P, E_P)$, the initial mapping τ , the depth of the circuit d, the number of qubits V_L , Tabu Search deals with one layer at a time, and searches at most d times. Starting from the initial mapping, we first delete the executable gates of the first layer under the initial mapping. Then, the edges of all the shortest paths of all the gates that are not executed in the current layer are added to the candidate set where at least one node is a node of the gate mapping. In the worst case, the shortest path length is $(|E_P|-1)$, and the candidate set size is $(|E_P|-1)$. Each SWAP will make the total distance between the gates smaller. In the worst case, the number of SWAPs is $(|E_P|-1)^{|E_P|-2}$, but our selection strategy will make the number of SWAPs significantly reduced. Our time complexity is $d * ((|E_P|-1))^{(|E_P|-2)}$, and the space complexity is the size of our candidate set (E_P-1) .

5 Experiment

The experiment in this paper is performed on a 2.3GHz Linux machine with 64G memory. This paper compares CSI algorithm and circuit transformation algorithm based on Tabu Search TST with the wghtgraph in [10] and the heuristic algorithm A^* in [25].

First, we compare the efficiency of initial mapping on τ_{optm} [25], τ_{CSI} and $\tau_{wghtgraph}$ [10]. In order to observe the results of these two initial mapping algorithms intuitively, we used the same circuit transformation A^* algorithm to compare the initial mapping algorithms [25].

Among 159 circuits, experiments show that within five minutes τ_{optm} can deal with 121 circuits, $\tau_{wghtgraph}$ can deal with 106 circuits, τ_{CSI} can deal with 131 circuits. There are 103 circuits that they can handle. Comparing $\tau_{wghtgraph}$ algorithm and τ_{CSI} algorithm, the $\tau_{wghtgraph}$ algorithm has 21 circuits with fewer auxiliary gates and 19 circuits with a small depth, and the τ_{CSI} algorithm has 54 circuits with fewer auxiliary gates and 60 circuits with a small depth, and they have 25 circuits with equal depth and 29 circuits with equal auxiliary gates. The auxiliary gates of the τ_{CSI} algorithm is relatively reduced by 22.4418%, and the depth is reduced by 11.2482%.

Comparing τ_{optm} algorithm and τ_{CSI} algorithm, the τ_{optm} algorithm has one circuit with fewer auxiliary gates and two circuits with a small depth, and the τ_{CSI} algorithm has 99 circuits with fewer auxiliary gates and 98 circuits with a small depth, and they have 4 circuits with equal depth and 4 circuits with equal auxiliary gates. The auxiliary gates of the τ_{CSI} algorithm is relatively reduced by 27.0219%, and the depth is reduced by 14.1242%. As shown in Table 1, there are 104 circuits. Three initial mapping algorithms are compared with the depth of the generated circuits under the A^* algorithm, and the number of auxiliary gates added. τ_{CSI}/τ_{optm} calculate the efficiency improvement of the former upon the latter, the formula is $(n_{optm} - n_{CSI})/n_{optm}$.

					$ au_{CSI}/ au_{wgtgraph} $
depth	168895	163422	145040	14.1241%	11.2482%
added	20439	19232	14916	27.0219%	22.4418%

Table 1. Compare τ_{optm} , $\tau_{wgtgraph}$, and τ_{CSI}

We compare the use of two indicators $(TST_{dep} \text{ and } TST_{num})$ that prioritize smaller depth and fewer auxiliary gates. The two indicators were used as objective functions, and 159 circuits were tested. The depth of the final circuit obtained by TST_{num} is 1.93% smaller than TST_{dep} on average, and the number of auxiliary gates added is 4.53% smaller on average. Inserting a SWAP gate, the circuit needs to add 3 CNOT gates, and the depth will be increased by 3. While the number of SWAP gates added is small, the circuit depth reduces accordingly. Thus we use SWAP quantity first to give better results.

Finally, we compare TST and wgtgraph. Since the wgtgraph algorithm only uses 2-qubit gates, it is impossible to compare the depth of the generated circuit, So we compared the number of SWAP gates added and compared the time. Since large circuits may not successfully handle for a long time, we consider it meaningless. This paper sets a five-minute timeout period and tested 159 circuits. TST_{num} only takes 461 seconds, TST_{dep} takes 485 seconds, and wgtgraph run 159 circuits in 1908 seconds, but only 98 files get results, 64 of them there are 66 circuits for small-scale circuits to get results, 49 medium-scale circuits only have 35 circuits for results, and no circuit output in 44 large circuits. Although Tabu Search can quickly produce results on large circuits, in contrast, more auxiliary gates are added. In 98 small-scale and medium-scale circuits with the results obtained by wgtgraph, the number of SWAP gates added by wgtgraph is 26.87% less than TST_{num} on average, and the number of SWAP gates added by wgtgraph is 24.89% less than TST_{dep} on average. Tabu Search can quickly output converted circuits on large circuits, but wqtqraph cannot get results in a short time. SABRE processes 159 circuits with a five-minute limit for each circuit. Only 23 circuits are successful for small-scale circuits, 6 for mediumscale circuits, and 1-scale for large circuits. The detailed results of the circuit comparisons are in the appendix.

benchmarks	#circ	TST_{num}		TST_{dep}		wgtgraph		SABRE	
	#-circ.	#succ.	time	#succ.	time	#succ.	time	#succ.	time
small	66	66	32	66	29	64	587	23	12996
medium	49	49	45	49	40	35	1183	6	13019
large	44	44	407	44	432	0	-	0	1340719
total	159	159	484	159	501	98	-	29	1366734

Table 2. Compare τ_{optm} , $\tau_{wghtgraph}$, and τ_{TST}

6 Conclusion

We proposes a CSI algorithm to generate high-quality initial mappings and a heuristic SWAP method TST based on Tabu Search to overcome the shortcomings of previous works. Experimental results showed that the initial mappings generated by CSI reduced the number of SWAP gates inserted and results could be obtained in a short time. Most small-scale and medium-scale circuits could be obtained in a few seconds. The result could be obtained within a few minutes, even for a large-scale circuit, but the cost of insertion might be equal to or more than wgtgraph. We introduced the look-ahead method to make each selected SWAP more in line with the constraints of the behind gates. In future, we would study how to reduce the number of auxiliary gates inserted as much as possible based on increasing speed, and apply the proposed method to more NISQ devices to get useful experimental data. We would introduce quantum noise to the circuits, since our simulate circuits ignore the noise generated by the circuit.
